Fragility hip fracture in the under 60s: a review of the literature

Gillian Janes, Laura Serrant, Magi Sque

Abstract

This critical review of the literature regarding the recovery experiences and healthcare needs of people under 60 following a fragility hip fracture seeks to identify the associated implications for nursing practice and inform care delivery. Forty papers were included following a structured database, citation and grey literature search and filtering of results in line with specified inclusion criteria.

Hip fracture is a common, serious and complex injury and an important cause of morbidity, mortality and rising healthcare costs worldwide. This review indicates that although commonly associated with the elderly, incidence and impact in the under 60s has been under-explored. Current health policy, professional and social norms almost exclusively focus on the elderly, surgical interventions and short-term outcomes, rendering the under 60s an inadvertently marginalised, relatively ‘silent’ sub-set of the hip fracture population.

Nurses must be aware however of the different recovery needs of this younger group. The limited evidence available indicates these include work related needs and long term physical and psychosocial limitations in this socially and economically active group. Priorities are identified for research to inform policy and practice meanwhile nurses can address the needs of this group by listening to and involving them and their families as healthcare partners.
INTRODUCTION

This paper explores the healthcare experiences and recovery needs of people under 60 years of age with fragility hip fracture within the context of the broader hip fracture population and the associated implications for nursing. It suggests that young fragility hip fracture patients are inadvertently marginalised as a result of academic, policy and professional discourses that focus on the elderly and short-term outcomes. It argues that nurses need greater awareness of the incidence, causation and impact of fragility hip fracture in younger patients to ensure their holistic needs are met and long-term recovery maximised.

Background

Hip fracture is a common, well-defined condition that threatens function and creates vulnerability (Proctor et al. 2008). The term includes all fractures of the proximal femur (Archibald 2003). This sudden, traumatic (Proctor et al. 2008), serious injury (van Balen et al. 2003) and threat to life (Olsson et al. 2007) is:

‘…a catastrophic sentinel event causing major secondary prevention implications.’ (Partridge & Marsh 2007, p122).

It requires a complex recovery (& Hutchinson 2005) and often involves a long hospital stay (Visschedijk et al. 2010). Fragility hip fractures predominantly occur in later life, average age 83 years (Healthcare Quality Improvement Partnership (HQIP), 2014) from low-energy injuries like a fall from standing height (Chesser et al. 2011). Associated with increased healthcare consumption (Leigheb et al. 2013,) and
significant burden on services (Holt et al. 2009), fragility hip fracture represents one of the biggest challenges this century (Parsons et al. 2014), costing the UK alone approximately £2billion annually (National Institute of Clinical Excellence, 2011).

Policy context

Trauma is already the commonest cause of death in the under 40s in England and Wales and life years lost through premature death and disability following injury is predicted to be the 2nd highest globally by 2020 (Trauma Audit and Research Network, 2016). Perhaps not surprisingly the recently established Trauma Audit and Research Network (TARN UK) addresses the most seriously injured individuals, with multiple, life threatening injuries. Young adults with fragility hip fracture, being more likely to survive and generally need less complex interventions are therefore not its focus. Further, economic recession following the global financial markets collapse of 2008 and an estimated £30 billion funding shortfall (Department of Health, 2014), means already overstretched services striving to deliver safe and effective care to more expectant patients, public and Government, with fewer resources (Mitchell et al, 2010).

Acknowledging the value of patient views has however resulted in strategies designed to enhance patients’ ability to inform policy-making. This is crucial because empowered patients recover better (Department of Health, 2001). Yet despite increasing demand for research taking account of the patient perspective (Gregory
2010) still few studies explore the patient perspective on fragility hip fracture (Clancy et al, 2015).

National Institute for Clinical Excellence (National Institute for Clinical Excellence) (2011) guidance covers all ages however the National Hip Fracture Database (for England, Wales, Northern Ireland and the Channel Islands), the largest prospective National Hip Fracture Database in the world (Gunasekera et al., 2010) only records fractures in people aged 60 and over. The database was established due to the public health threat osteoporosis and fragility fractures present for older people (Partridge & Marsh, 2007); and assumptions that hip fractures in the under 60s were mainly due to high impact injury, underlying bone or other predisposing health conditions (Plant, 2010). There are however no international criteria for recording hip fracture with considerable variation in recording between nations worldwide.

Although the UK has one of the highest hip fracture rates in Europe (Mitchell et al. 2010), fragility hip fracture is a relatively rare injury in young adults who represent a small subset of all hip fractures. Many years ago however, Boden et al (1990) argued the significance of hip fracture in this working-age group may be underestimated despite potentially profound social and economic implications, at societal and individual level (Holt et al. 2008a).

**AIM AND SCOPE OF THE REVIEW**

The aim of this review was to examine the literature on the recovery experiences and healthcare needs of the under 60s following fragility hip fracture to inform future care delivery.
Search strategy/method

Electronic database, citation (Garrard 2014) and grey literature (Higgins & Green 2011) searching was undertaken. Major healthcare databases covering an appropriate range of journals, topics and concepts i.e. Medline, Cinahl, AMED, ASSIA, PsychInfo and Embase and the British Library PhD thesis database were searched. Search criteria are presented in Table 1 and the key words used include: hip fracture surgery/internal fixation, falls, low velocity injury, patient stories, patient experience and outcome assessment, rehabilitation and recovery, quality of life, quality of care, middle age (45-64 years), care pathways, post-traumatic stress disorder and self-concept. Using Boolean operators, truncation and ‘wildcard’ symbols maximised retrieval of relevant papers.

Only papers published in English were included. Initial searches were limited to the last 10 years and the under 60s but yielded so little material these were extended to include the over 60s and papers published from 1970s to December 2016. Grey
literature searching included: Department of Health, NHS England, NHS Improving Quality, King’s Fund and World Health Organisation publications. This provided policy and contextual information published outside the research literature. Citation searching continued until no new papers were identified and familiarity with the research field or ‘owning the literature’ (Garrard 2014) was achieved. Duplicates were deleted then results filtered to remove irrelevant papers based on reading the title, abstract and/or full text. All those addressing one or more of the search terms, over 4100 results, were screened.

Sources addressing any of the inclusion criteria were included as so little material was found specifically addressing the under 60s. Where clarity was lacking on the scope of papers, for example regarding age related criteria, or no comparable information was published specifically addressing the under 60s, these papers were included to maximise retrieval of all potentially relevant material. Although the surgical aim for young hip fracture patients is generally internal fixation rather than hip replacement (Thuan and Swiontkowski, 2008), emergency joint replacement is sometimes necessary. For this reason, studies addressing patient experience of emergency hip replacement were included and those concerning scheduled hip replacement excluded.

RESULTS

The 40 papers meeting the selection criteria and on which the following discussion is based are summarised in Table 2.
Table 2: Summary of papers included in the review

DISCUSSION

Two themes emerged. The first: causative factors, comprised three sub-themes: age-related incidence, underlying health and lifestyle factors and injury velocity. The second theme: outcome evaluation comprised four sub-themes: differentiated evaluation by patient sub-group, impact on mobility, psychosocial impact and recovery enabling factors. The review findings will therefore be discussed using these headings.

Theme 1: Causative factors

Age-related incidence

There is consensus that hip fracture risk and increasing age are positively correlated. However, whilst most research uses 18 or 20 years of age as the lower limit, the upper age used to define ‘young’ or ‘early’ hip fracture varies considerably. 60 or 65 years of ages is commonly used as the upper parameter for study inclusion/exclusion purposes e.g. Karantana et al. (2011); although some (Nieves et al., 2010; Leavy et al., 2013) used 50 years and over when studying fragility fracture in younger people. Al-Ani et al. (2013) differentiated between younger groups, defining 50-69 years as middle age and 20-49 years of age as young, but this is rare. Age 50 however is an arbitrary dividing line after which fractures in women particularly may be attributable to post-menopausal osteoporosis (Verettas et al., 2002). In one of few studies specifically addressing hip fracture in young people, Protzman & Burkhalter (1976) justified their 20-40 years of age inclusion criteria based on the femur being physiologically mature but without physiological atrophy
between these ages. Nevertheless, the varied age-related parameters used in empirical studies to define young hip fracture, make direct comparison extremely difficult.

Underlying health and lifestyle factors

Nieves et al. (2010) reported an exponential increase in fragility fracture with increasing age in the over 50s. This predominantly affected women and was therefore often associated with osteoporosis. However, statistical analysis of over half a million women (Banks et al., 2009) could not make valid pre and post-menopausal comparisons due to too few participants of pre-menopausal age. Researchers (Al – Ani et al., 2013; Karantana et al. 2011; Rohde et al. 2008; Swiontkowski et al. 1984) agree that lifestyle factors like smoking and high alcohol intake increase the incidence of ‘early’ hip fracture.

Based on an almost three times greater incidence of osteoporosis, lower bone mass index, and more frequent co-morbidities than controls, Rohde et al. (2008) large matched control study of the over 50s characterised hip fracture patients as older with complex underlying conditions. Further Karantana et al. (2011) reported that fractures in working age (under 65 years) women following a minor fall were pathophysiological. This confirmed findings by Holt et al. (2008a) and the consensus that isolated hip fractures in the under 65s were mainly osteoporotic (National Institute for Clinical Excellence 2011).
Court-Brown & Caesar (2006) suggested hip fracture epidemiology is changing rapidly though with considerably more osteoporotic fractures than previously thought. Karantana et al. (2011) found the first significant increase in age-related hip fracture in women at 45 years of age, five years before osteoporosis screening commonly begins, with mortality in younger women with hip fracture 46 times that of the female population. To put this in perspective, the 13 million women aged over 45 years of age in the UK represent one fifth of the total population (British Menopause Council 2011). Bone density appraisal is recommended post fracture (National Institute for Clinical Excellence 2011) but Oetgen et al. (2009) argued that endocrine assessment should be added because metabolic abnormalities correlated poorly with bone density. Thus, reliance on bone density measurements may contribute to under-estimation of fracture risk for some patients (Aspray 2013). Even this recommendation though focuses on post-fracture treatment and secondary prevention, limiting the potential for reduction in preventable fractures using primary prevention interventions.

Whilst fragility fracture often signals underlying ill health (Chesser et al. 2011), Al – Ani et al. (2013) contradicts this in finding most of their 185 participants under 50 years were in good health. Thus, although evidence in the under 60s is very limited, there is some indication that current accepted norms regarding the underlying causes of fragility hip fracture in younger people warrant further investigation.

Injury velocity
The few studies specifically focusing on young adults with isolated hip fracture that have been undertaken consistently reported high velocity trauma resulting in multiple injuries and poor prognosis (Protzman & Burkhalter 1976; Swiontkowski et al. 1984; Thuan & Swiontkowski 2008). Robinson et al. (1995) concur, reporting hip fracture in people 20-40 years of age most commonly occurred in men following high-energy trauma and this was further confirmed in the under 50s by Verettas et al. (2002).

Verettas et al. (2002) however also reported that approximately a third of fractures followed low velocity trauma such as a minor fall but potential causes for these fragility fractures in this younger group were not explored. Al-Ani et al. (2013) further highlighted the impact of low energy trauma in the under 50s, reporting that 80% of all fractures at this age were caused by low energy trauma like a fall from the same level, cycling or ice-skating. These two studies therefore specifically challenge the accepted norm that hip fracture in the under 50s is mostly the result of high velocity injury or underlying illness.

**Theme 2: Outcome evaluation**

Differentiated evaluation

The heterogeneity of the hip fracture population, complex recovery pathway and contextual nature of impact, have created calls for evaluation of outcomes to be differentiated between sub-groups within the broader hip fracture population. Differentiation factors such as: mode of injury, surgical procedure and context/quality
of life issues post fracture have been proposed to enable the development of more effective, targeted interventions (Eastwood et al. 2002; Montin et al. 2002).

Epidemiologic and outcome studies have enhanced understanding of hip fracture outcomes and recovery. However many such studies focus on the over 65s (see for example Ariza Vega et al. 2014; Kondo et al. 2014) meaning outcomes for the under 60s are less often explored. In addition, functional and physiological evaluations remain commonest (Bertram et al. 2011; Santamaria et al. 2003). Even studies that do include the under 65s, use primary evaluation measures of: mortality (Australia and New Zealand Hip Fracture Registry 2012; Eastwood et al. 2002; Holt et al. 2008a; Holt et al. 2008b; Holt et al. 2009); post injury institutionalisation or place of residence (Australia and New Zealand Hip Fracture Registry 2012; Castellini et al. 2015; Eastwood et al. 2002; Holt et al. 2008a, Holt et al. 2008b); length of hospital stay (Australia and New Zealand Hip Fracture Registry 2012; Castellini et al. 2015; Holt et al. 2008a; Holt et al. 2008b; Holt et al. 2009); further falls (Australia and New Zealand Hip Fracture Registry 2012; Hansson et al. 2015); mobility (Eastwood et al. 2002; Griffiths et al. 2015; Hansson et al. 2015, Holt et al. 2008a, Holt et al. 2008b) and re-operation rates (Gjertsen et al. 2011).

Whilst these are important measures they may not best reflect holistic outcome for the young fragility hip fracture population who are less likely to experience these sequelae because of generally higher levels of pre-injury health and self-efficacy. In addition, this group are more likely to experience other challenges associated with
their relative youth, such as returning to work or caring responsibilities, that are not currently evaluated.

Foss et al. (2009) recommended future fragility hip fracture outcome studies should also stratify individuals by surgical procedure, as pain levels were highest following internal fixation. This is the treatment of choice in the under 50s. Hip replacement is avoided in this younger group wherever possible due to their higher activity levels and longer need of the replacement joint (Thuan & Swiontkowski 2008) despite higher incidence of femoral head necrosis and non-union (Verettas et al. 2002). However, although involving only elderly participants, a randomised study of 450 patients over 10 years (Leonardsson et al. 2010) found internal fixation did not give better function or pain control than hip replacement, further supporting calls for outcome evaluation by treatment and age sub-group by Foss et al. (2009) and Coughlin et al. (2016). These studies also reinforce previous findings in the over 60s by Gjertsen et al. (2008) who recommended research exploring issues like pain and quality of life in different sub-groups of the hip fracture population to improve treatment quality. This in turn, reflects the earlier recommendation by Swiontskowki et al. (1984) regarding separate evaluation of femoral neck fractures associated with multiple trauma in young people.

**Impact on mobility**

Substantial, sometimes permanent reduction in mobility is often reported in the elderly but its impact in younger people is equally important as mobility is closely
connected with pain and maintaining independence at any age. Bertram et al. (2011) reported that 42% of participants in the 25 studies they reviewed had not regained pre-fracture mobility a year post injury, illustrating the extended impact of hip fracture on mobility even for young people. Although ability to walk was important (Griffiths et al., 2015), restricted leg movements hampering other activities such as gardening or using transport, also impacted negatively on daily activities (Bertram et al., 2011).

Pain is a very commonly reported patient outcome post hip fracture although much of the literature addresses the over 65s. For example, Archibald (2003) found this focused on acute pain immediately post injury and in the trauma unit. Olsson et al. (2007) confirmed this, although Vilardo & Shah (2011) reported unexplained, chronic pain following hip replacement, which is the treatment of choice for some younger hip fracture patients, is as an overlooked issue causing distress, substantial loss of function and societal productivity. In addition, a survey across two hospitals, of patients averaging two-years post-surgery, reported pain was one of the greatest difficulties following sub-acute care in the over 65s (Kondo et al. 2014). In a rare study involving young hip fracture patients, Swiontkowski et al. (1984) however also reported participants experiencing mild to moderate pain and loss of function up to three-years post-surgery. Furthermore, an extensive literature review across the age continuum (Bertram et al. 2011) found enduring pain; with 47% of hip fracture patients reporting pain one or more years post fracture, of which 26% was moderate to severe.
The literature also predominantly focuses on short-term outcomes in the elderly (see for example: Ziden et al. 2008; Kondo et al. 2014; Chung et al. 2009). This is partially driven by government policy. For example, of six financially incentivised quality measures for hip fracture care in the UK, all but two concern acute care and relatively short-term metrics concerning walking ability at 30 and 120 days (Department of Health, 2014). Long-term disability post hip fracture is grossly underestimated (Bertram et al., 2011). These authors estimated 29% of hip fractures result in long-term disability but found determining this complex. No single Patient Reported Outcome Measure (PROM) could evaluate care quality for all hip fracture patients (Griffiths et al. 2015; Moppett et al. 2012). The commonly used Oxford Hip Score (OHS) was designed to quantify disability from degenerative joint disease rather than traumatic injury and EQ-5D is a generic quality of life measure covering health domains that hip fracture patients consider important (Parsons et al. 2014) but there is little evidence of response to Parker’s (2004) call over a decade ago for more unconventional outcome measures.

The under 60s represent working age adults who commonly have other responsibilities so the potential economic and social implications of fragility hip fracture in this group are profound (Holt et al. 2008a). Bertram et al.’s (2011) claim regarding underestimation of the long-term disability associated with hip fracture supported previous findings in the under 50s (Verettas et al. 2002). Their participants reported long term absence from work and disability due to reduced joint function, although isolated examples of the fracture prompting return to positive roles and activities were found by Montin et al. (2002). Janes (2016) findings supported both these previous findings whilst emphasising the importance of personal context for
successful rehabilitation and the need to move beyond the traditional focus on visible impairments to psychological and social aspects of illness and disability as emphasised in the World Health Organisation (WHO) ICID-2 definition of disability (Wade 2000).

Psycho-social impact

Historically the success or failure of orthopaedic interventions was determined and reported by surgeons not patients (Ashby et al, 2009). Further, a recent randomised controlled trial involving 122 hip fracture patients (Martin-Martin 2014) reported that self-perception and quality of life impact are less explored. Adopting a bio-psychosocial model of care could enhance patient care and should routinely include PROMs for psychological and social factors not traditionally addressed (Vilardo & Shah, 2011). Larner (2005) argued however that the psychological challenges faced by patients with new disability or recovering from major illness were considered vague or difficult and were therefore neglected by medical approaches. Similarly, Proctor et al. (2008) claimed little is known of the impact of psychological factors on hip fracture recovery and rehabilitation.

A recent qualitative study aiming to address the current gap in the literature regarding the recovery experiences and impact of fragility hip fracture in the under 60s reported long term psycho-social impact up to 10 years post fracture (Janes 2016). This supported previous findings by Karlsson et al. (2012) that the early post fracture phase meant having to come to terms with loss of control and an unfamiliar
environment. Janes (2016) also found Fear of Falling (FOF) was common. Chung et al. (2009) reported evidence that FOF, which they found in a substantial minority of elderly hip fracture participants, and Post-Traumatic Stress Disorder (PTSD) are overlapping concepts. This suggests some patients with FOF may actually be exhibiting PTSD. A systematic review (Visschedijk et al. 2010) has since indicated that 50% or more of all hip fracture patients suffer FOF, illustrating the potential scale of this issue across the age range, although adequate measures have not been validated for hip fracture patients. These studies reflect previous findings in the over 65s, such as Ziden et al. (2008) description of hip fracture as a ‘life- breaking event’ because of the multidimensional consequences and profound psychological and social impact it had on their participants:

‘…the fracture seemed not only to break the bone but also to cause social and existential cracks…’ (p801)

which were not sufficiently taken into account.

The importance of acknowledging the hip fracture’s impact from the patient’s perspective for the under 60s was acknowledged by Janes (2016). This supported previous findings by Leonardsson et al. (2010) in respect of the over 70s. Both studies highlighting the particular importance of evaluating longer-term quality of life and functional outcomes. This was despite the difficulty of isolating the impact of health conditions developed post fracture from that of the fracture itself in longer-term studies noted by Bertram et al. (2011).
Knowing what patients themselves consider the most important aspects of care was also found to be crucial in a study of total hip replacement patients aged between 22 and 79 years (Montin et al. 2002) and was further supported by Janes (2016) study of the under 60s whose had primarily undergone internal fixation. Janes (2016) also reported positive outcomes of having their recovery story heard for hip fracture patients. This also confirmed previous work with major trauma survivors (Morse & O’Brien 1995) which uncovered the therapeutic effect that reflecting on their experiences had on participants, in redefining self as a disabled person. This finding was further confirmed in 2007 when Olsson et al highlighted the benefits for older patients of being listened to. This can enable patients to support service improvement as illustrated by a narrative case study presenting a 60-year old lady’s experience of fragility hip fracture in her own voice to support service improvement (Pownall 2004). Oberg et al. (2005) continued to urge listening to patients because this can provide key information not captured using quantitative methods. Similarly, a small study in the over 65s found that professionals need to listen to patient perspectives to enable person centred care (Mauleon et al. 2007).

Factors enabling recovery

Physical and psychosocial enablers of recovery have been reported. With the exception of Janes (2016) these almost exclusively focus on the over 60s and hip replacement rather than internal fixation, the commonest treatment of choice for under 65s. Key aspects of Janes (2016) findings mirror those of previous studies with older patients. These include the need for intensive rehabilitation to enable return to pre-injury quality of life (Pownall 2004), despite the overly mechanistic
emphasis on visible impairments, function, patient behaviour and activities, rather than individual’s psychological needs suggested by Wade (2000). Similarly Young & Resnick (2009) also found that over 65s take account of professional advice, are positive about recovery and resilient. This, together with seeking help (Schiller et al. 2015) and determination and maintaining perspective (Young & Resnick 2009) were found to support recovery in older patients as well as the under 60s in Janes’ (2016) study.

Janes (2016) also found however that rehabilitation adjustment for young patients with different needs was lacking. This mirrored similar findings by Roding et al. (2003) regarding young stroke survivors. In addition, Eastwood et al. (2002) called for research focusing on post discharge and longer-term recovery as some younger hip fracture patients had poorer outcomes at six-months. The need for more social support and physiotherapy was identified by Hansson et al. (2015) in an annual cohort study of 664 hip fracture patients and was further supported by Janes’ (2016) findings in the under 60s. These two studies reflected similar findings in the over 65s by Young & Resnick (2009).

Reflecting similar findings in the over 65s by Young & Resnick (2009), Janes (2016) reported that support from family and friends was important for recovery in the under 60s and that members of their networks found recovery challenging, not always understanding less visible sequelae like fatigue. These results support those of Schiller et al. (2015) in respect of hip fracture patients over 60 years and Roding et al. (2003) concerning young stroke survivors who also called for more involvement of families in the rehabilitation process because of its impact on them. These issues are
of particular importance for the under 60s as Janes (2016) found evidence they can have an impact on social and work relationships with individuals not necessarily able to return to social and work roles as soon as members of their social networks expect.

**LIMITATIONS OF THE REVIEW**

As a result of the extremely limited evidence specific to the under 60s and their experience of fragility hip fracture and recovery and a lack of consistency in the focus or reporting of relevant studies, for example in terms of age related inclusion/exclusion criteria, this was a pragmatic, exploratory review. It therefore drew on studies meeting any of the inclusion criteria to identify potentially transferable evidence. As a result, its conclusions are tentative and the need for further more specific work on fragility hip fracture in the under 60s is recognised. In addition, whilst drawing on the international literature, the review was also limited to papers published in English after 1970. Some of the evidence reviewed is dated but illustrates the still limited contemporary evidence in respect of fragility hip fracture in the under 60s despite calls for further exploration going back many years.

**CONCLUSION AND IMPLICATIONS FOR PRACTICE**

Not surprisingly, the rising incidence of osteoporosis and considerable burden of fragility hip fracture in the elderly mean these issues receive significant attention. However, despite a large body of knowledge regarding the causes, treatment and clinical outcomes of fragility hip fracture, little is known of the long term outcomes or
patient experience in the under 60s. This paper argues young adults with fragility hip fracture are an under-represented, relatively ‘silent’ subset of the hip fracture population. The characteristics of this patient group: relatively small numbers; youth and general absence of co-morbidities and less complicated recovery as gauged by commonly used short term outcome measures, position fragility hip fracture in the under 60s outside accepted norms with their specific recovery needs minimally addressed. Nurses must be aware of the different recovery needs of this younger group to enable effective care delivery. The limited evidence available indicates these include work-related issues and long-term physical, psychological and social limitations.

This paper therefore provides the justification for:

- further research exploring the recovery experiences and needs of the under 60s following a fragility hip fracture;
- raising healthcare staff and policy makers’ awareness of fragility hip fracture in the under 60s and developing policy and practice to address this;
- reviewing the appropriateness of current hip fracture outcome measures for the under 60s;
- reviewing current healthcare policy and service delivery to prevent further marginalisation or ‘silencing’ of this client group.

Meanwhile, listening to and involving patients and their families as part of the healthcare team could help nurses to ensure their needs are more effectively addressed.
