Abstract
We have previously reported a synthetic Laponite crosslinked poly N-isopropylacrylamide-co-N', N'-dimethylacrylamide (NPgel) hydrogel, which induces nucleus pulposus (NP) cell differentiation of human mesenchymal stem cells (hMSCs) without the need for additional growth factors. Furthermore NP gel supports integration following injection into the disc and restores mechanical function to the disc. However, translation of this treatment strategy into clinical application is dependent on the survival and differentiation of hMSC to the correct cell phenotype within the degenerate intervertebral disc (IVD). Here, we investigated the viability and differentiation of hMSCs within NP gel within a catabolic microenvironment. hMSCs were encapsulated in NPgel and cultured for 4 weeks under hypoxia (5% O2) with ± calcium, interleukin-1β (IL-1β), and tumor necrosis factor alpha (TNFα) either individually or in combination to mimic the degenerate environment. Cell viability and cellular phenotype were investigated. Stem cell viability was maintained within hydrogel systems for the 4 weeks investigated under all degenerate conditions. NP matrix markers: Agg and Col II and NP phenotypic markers: HIF-1α, FOXF1, and PAX1 were expressed within the NPgel cultures and expression was not affected by culture within degenerate conditions. Alizarin red staining demonstrated increased calcium deposition under cultures containing CaCl2 indicating calcification of the matrix. Interestingly matrix metalloproteinases (MMPs), ADAMTS 4, and Col I expression by hMSCs cultured in NPgel was upregulated by calcium but not by proinflammatory cytokines IL-1β and TNFα. Importantly IL-1β and TNFα, regarded as key contributors to disc degeneration, were not shown to affect the NP cell differentiation of mesenchymal stem cells (MSCs) in the NPgel. In agreement with our previous findings, NPgel alone was sufficient to induce NP cell differentiation of MSCs, with expression of both aggrecan and collagen type II, under both standard and degenerate culture conditions; thus could provide a therapeutic option for the repair of the NP during IVD degeneration.

KEYWORDS
degeneration, hydrogel, intervertebral disc, regeneration
1 INTRODUCTION

Low back pain (LBP) is a common debilitating clinical condition that affects 80% of the population at some point during their lifetime. Although the etiology remains unclear, it is widely accepted that intervertebral disc (IVD) degeneration is a major cause of LBP. Morphologically the IVD is composed of three distinct regional structures: the cartilaginous endplates (CEPs); the annulus fibrosus (AF), and the central gelatinous nucleus pulposus (NP). The NP is rich in proteoglycans (mainly aggrecan) and collagen type II. The IVD functions to separate the vertebrae and facilitate a range of spinal movements.

Degeneration of the IVD is characterized by a loss of matrix due to altered cellular metabolism and an imbalance between matrix synthesis and matrix breakdown. As IVD degeneration advances, collagen type II in the NP is gradually replaced by the more fibrous collagen type I. In addition, overall proteoglycan composition is altered by a reduction in synthesis of aggrecan, reducing the water binding capacity, which results in a condensed and more fibrous NP. Furthermore, matrix degradation is accelerated by upregulation of matrix degrading enzymes, matrix metalloproteinases (MMPs), and a disintegrin and metalloproteinase with thrombospondin motifs (ADAMTS). These changes in the matrix are also accompanied by cellular changes with increased apoptosis and senescence displayed by NP cells. Collectively, these events result in a loss in the structural integrity of the NP and overall reduced disc height decreasing the capacity to withstand load. The subsequent asymmetric distribution of load on degraded regions leads to the formation of tears and fissures through the AF region of the disc. These fissures can lead to disc herniation and enable the ingrowth of nerves and blood vessels, which are associated with the sensation of chronic LBP.

The mechanisms behind IVD degeneration are attributed to an imbalance between anabolic and catabolic processes. Inflammatory cytokines, particularly interleukin-1β (IL-1β) and tumor necrosis factor alpha (TNFα), are increased during disc degeneration, and have been implicated as key factors in the pathogenesis of disc degeneration. Calcification of the IVD is also commonly present in aging and end stage degeneration, thus is considered to cause, or at least promote the process of IVD degeneration. It has been suggested that calcification of the CEP leads to disc degeneration by acting as a barrier to nutrient transport and decreasing nutrient availability in the disc. Recent studies indicate that increased extracellular calcium may play a role in disc degeneration by activating the extracellular calcium-sensing receptor CaSR, leading to increased ADAMTS activity. Ultimately, the mechanisms responsible for the calcification of the disc are unclear and, currently there is no scientific consensus on whether calcification causes disc degeneration by altering the disc metabolism, or whether degenerative changes in the IVD alters its properties and leads to mineral deposition.

2 METHODS

2.1 Hydrogel synthesis

Laponite crosslinked pNIPAM-co-DMAc (NPgel) hydrogel was prepared as previously described. Briefly a 10 mL exfoliated suspension of Laponite clay nanoparticles (25-30 nm diameter, <1 nm thickness) (BYK Additives Ltd, Cheshire, UK) in 18 mL deionized H2O was prepared. To 10 mL exfoliated clay suspension, 0.773 g N-isopropylacrylamide 99% (NIPAM) (Sigma, Poole, UK); 0.117 g N, N'-dimethylacrylamide (DMAc) (Sigma, Gillingham, UK), and 0.01 g 2-2'-azobisobutyronitrile (AIBN) (Sigma, Poole, UK) were added, mixed well, and strained through 5 to 8 μm pore filter paper, polymerization was performed at 80°C for 24 hours. Hydrogel suspension was cooled to 38°C to 39°C prior to cell incorporation.
Eagle Medium media (Life Technologies, Paisley, UK) supplemented with 10% v/v heat inactivated fetal calf serum (FCS) (Life Technologies, Paisley, UK), 100 U/mL Penicillin (Life Technologies Paisley, UK), 100 μg/mL Streptomycin (Life Technologies Paisley, UK), 250 ng/mL amphotericin (Sigma, Poole, UK), 2 mM glutamine (Life Technologies, Paisley, UK), and 10 μg/mL ascorbic acid (Sigma, Poole, UK) (complete cell culture media). Following expansion in monolayer to passage 7, 1 × 10^6 cells/mL cells were mixed with the hydrogel suspension at 38°C to 39°C and 300 μL added into the center wells of a sterile 48 well culture plate leaving the outer wells void of hydrogel, acellular controls were also established as described previously. All acellular and hMSC hydrogel scaffolds were cultured in 1 mL complete cell culture media in addition to known catabolic factors: ± calcium (2.5 mM and 5.0 mM CaCl₂), 10 ng/mL IL-1β and 10 ng/mL TNFα either individually or in combination to mimic the degenerate microenvironment and incubated at 37°C, 5% CO₂ and maintained in culture for up to 4 weeks in an oxygen controlled glove box (Coy Lab products, York, UK) at 5% O₂. Complete culture media was replaced every 2 to 3 days with application of fresh cytokines and CaCl₂. Samples were removed for the initial 7 days for the analysis of metabolic cell activity, and following 4 weeks for histological assessment of matrix deposition and hMSC differentiation and matrix degrading enzyme production using immunohistochemistry (IHC).

2.3 Cytocompatibility of hMSC cultured in presence of cytokines and Ca²⁺

The metabolic cell activity of hMSCs incorporated in solidified pNIPAM-DMAc-Laponite hydrogels, cultured in 5% O₂ at a density of 1 × 10⁶ cells/mL were assessed using Alamar Blue assay (Life Technologies, Paisley, UK) using the manufacturers protocol following 7 days within the different culture conditions. The absorbance was recorded using a fluorescence microplate reader (CLARIOstar, BMG LABTECH, Aylesbury, UK) at a fluorescence excitation wavelength of 590 nm. Relative fluorescence units (RFU) were recorded for cellular hydrogel scaffolds and normalized to the RFU of acellular control scaffolds as an indication of cytotoxicity/proliferation.

2.4 Histological analysis

Matrix deposition was investigated in hydrogels cultured with or without cells under the varied culture conditions following 4 weeks. Triplicate samples were removed from culture and fixed, processed to wax and 4 μm sections prepared for histological and immunohistochemical analysis as described previously. Sections were assessed using histological stains: H&E, Alizarin red, Alcian blue, and Masson’s trichrome as described previously. All slides were examined with an Olympus BX51 microscope and images captured by digital camera and Capture Pro OEM v8.0 software (Media Cybernetics, Buckinghamshire, UK). Histological sections were analyzed, and images were captured to document their histological appearance and cellular staining patterns. Calcium deposition was measured as a percentage staining area using ImageJ 1.5i software. The whole field of view was used as the area of interest. The image was split into red, green, and blue using RGB stacks and the threshold was applied at a range of 0 to 147 using the blue channel which gave the best contrast for red (calcium) staining; the percentage area of the red staining was then measured.

2.5 Immunohistochemical analysis

IHC was performed on hMSCs taken from monolayer culture prior to hydrogel encapsulation to serve as time zero controls. Cytospins were formed as described previously. Caspase 3 was utilized as a marker of apoptosis for IHC investigation as an indication of cell viability of hydrogel encapsulated hMSCs under the different culture conditions. NP matrix markers: aggrecan, collagen type II, chondroitin sulphate, and NP phenotypic markers: HIF1α, PAX1, FOXF1 together with NP negative markers: collagen type I and osteopontin were selected for IHC investigation to assess differentiation capacity of hMSCs within monolayer culture and following culture within NPgel under the different culture conditions. To determine the influence of culture conditions on MSCs cultured within NPgel on the production of matrix degrading enzymes, IHC for MMP3, MMP13, and ADAMTS 4 were investigated. Immunohistochemical analysis for the catabolic cytokine IL-1β and its receptor IL-1RI were investigated to determine the influence of NPgel culture and whether a catabolic phenotype was induced within hMSCs cultured in presence of cytokines and Ca²⁺. IHC was performed as previously described specific antibody details provided in (Table 1). Briefly, 4 μm paraffin sections were dewaxed, rehydrated, and endogenous peroxidase-blocked with hydrogen peroxide (Sigma, Aldrich, Poole, UK). Following washes in tris-buffered saline (TBS; 20 mM tris, 150 mM sodium chloride, pH 7.5) sections were subjected to antigen retrieval methods where required (Table 1). Following TBS washing, nonspecific binding sites were blocked at room temperature for 90 minutes with 25% w/v serum (Abcam, Cambridge, UK) (Table 1) in 1% w/v bovine serum albumin in TBS. Sections were incubated overnight at 4°C with primary antibodies (Table 1), or mouse or rabbit IgG controls (Abcam, Cambridge, UK). Sections were washed in TBS and incubated with 1:500 biotinylated secondary antibody (Table 1), washed and incubated in HRP-streptavidin biotin complex (Vector Laboratories, Peterborough, UK). Sections were washed again in TBS prior to 20-minute incubation in 0.65 mg/mL 3,3-diaminobenzidine tetrahydrochloride 0.08% v/v hydrogen peroxide (Sigma Aldrich, Poole, UK) in TBS. Sections were counterstained with Mayer’s Hematoxylin (Leica Microsystems, Milton Keynes, UK), dehydrated in industrial methylated spirit (Fisher, Loughborough, UK), cleared in SubX (Leica Microsystems, Milton Keynes, UK) and mounted in Pertex (Leica Microsystems, Milton Keynes, UK). All slides were visualized using an Olympus BX51 microscope and images captured by digital camera and Capture Pro OEM v8.0 software (Media Cybernetics, Buckinghamshire, UK). IHC staining was evaluated by counting total immunopositive
and immunonegative cells for each section and immunopositive cells expressed as a percentage of total count.

2.6 Data processing and statistical analysis

All tests were performed at least in triplicate. Data was nonparametric and hence statistical comparisons were performed by Kruskal-Wallis with pairwise comparisons (Conover-Inman), statistical significance was accepted at $P \leq 0.05$.

3 Results

3.1 Cytocompatibility of hMSCs in the presence of cytokines and free Ca$^{2+}$

Alamar blue assay, as a measure cell viability was utilized, metabolic cell activity was assessed over 7 days in culture in NPgel under nondegenerate control conditions and in the presence of cytokines and Ca$^{2+}$. No significant difference in metabolic cell activity was detected over the 7-day culture period where hMSCs were incorporated into NPgel constructs cultured in any of the experimental conditions (data not shown).

Low levels of apoptosis were observed in MSCs cultured in NPGels under nondegenerate standard conditions and the standard culture experimental groups treated with cytokines IL-1β and TNFα alone, with no significant difference in the number of caspase 3 immunopositive cells compared to the nondegenerate standard control (Figure 1). Where IL-1β and TNFα were used in combination there was a significant increase in the number of immunopositive cells compared to the nondegenerate standard control ($P = .0040$) (Figure 1). A significant difference in the number of caspase 3 immunopositive cells was observed between the standard nondegenerate conditions and each of the experimental groups cultured with CaCl$_2$ (2.5 mM CaCl$_2$ vs standard culture, $P = .0003$; 5 mM CaCl$_2$ vs standard culture, $P = .0021$) (Figure 1). While cotreatment with 2.5 mM CaCl$_2$ with IL-1β showed significantly fewer caspase 3 positive cells than treatment with 2.5 mM CaCl$_2$ alone ($P = .0023$) (Figure 1), as did cotreatment of 5 mM CaCl$_2$ with TNFα compared to treatment with 5 mM CaCl$_2$ alone ($P = .0457$) (Figure 1). Although no culture condition showed greater than 30% caspase 3 positive cells within NPgel cultures indicating changes were relatively small (Figure 1).

3.2 Histological and immunohistochemical evaluation of matrix components in hMSCs in the presence of cytokines and free Ca$^{2+}$

Proteoglycan deposition was observed by alcian blue staining within hydrogels encapsulated with hMSCs (Figure 2), while some background staining was observed in no cell control hydrogels increased staining was observed in those hydrogels containing cells (Figure 2). Monolayer hMSCs extracted from culture prior to hydrogel encapsulation showed no immunopositivity for aggrecan (Figures 2 and 3). Cellular immunopositivity for aggrecan was significantly increased in hMSC cells cultured in NPgel under nondegenerate standard culture conditions in comparison to the monolayer controls ($P = .0112$) (Figures 2 and 3). No difference in immunopositivity was observed between the nondegenerate standard culture conditions and culture with cytokines and free Ca$^{2+}$ (Figures 2 and 3). Collagen deposition was observed, by Masson’s trichrome staining and immunohistochemical detection of collagen type II and collagen type I (Figure 2). Monolayer hMSCs extracted from culture prior to hydrogel encapsulation showed low levels of immunopositivity for collagen type II and collagen type I (Figures 2 and 3). An increase in cellular immunopositivity for collagen type II was observed in hMSC scaffolds under nondegenerate standard control conditions in comparison to monolayer controls ($P = .0002$) (Figure 3). A significant decrease in the percentage of immunopositive cells for collagen type II was observed.

5 mM CaCl$_2$ vs standard culture, $P = .0021$ (Figure 1). While cotreatment with 2.5 mM CaCl$_2$ with IL-1β showed significantly fewer caspase 3 positive cells than treatment with 2.5 mM CaCl$_2$ alone ($P = .0023$) (Figure 1), as did cotreatment of 5 mM CaCl$_2$ with TNFα compared to treatment with 5 mM CaCl$_2$ alone ($P = .0457$) (Figure 1). Although no culture condition showed greater than 30% caspase 3 positive cells within NPgel cultures indicating changes were relatively small (Figure 1).
in the cultures with 5 mM CaCl₂ alone \( (P = .0007) \), however, this decrease was significantly reduced with cotreatment with either IL-1β or TNFα in combination with 5 mM CaCl₂ \( (P = .0107) \) (Figure 3). No difference was observed in cellular immunopositivity for collagen type I in hMSC scaffolds cultured under nondegenerate control conditions compared to standard media controls. A significant increase in the percentage of immunopositive cells for collagen type I was observed in all the cultures containing 2.5 mM CaCl₂ \( (P = .0034) \) and 5 mM CaCl₂ \( (P = .0062) \) (Figure 3) with no difference seen following stimulation with cytokines (Figure 3).

**Calcium deposition as confirmed by Alizarin red staining (Figure 4), was observed in hMSC cultured in NPgel under standard culture conditions and those containing nondegenerate and degenerate culture conditions. A significant increase in the percentage staining of calcium deposition was observed in experimental groups cultured in media supplemented with 2.5 mM CaCl₂ \( (P = .0009) \) and 5 mM CaCl₂ \( (P < .0001) \) compared to nondegenerate standard media controls, with a dose-dependent effect seen \( (P = .0068) \) (Figure 4). Calcium deposition was also significantly increased compared to the CaCl₂ treated no cell controls following 5 mM CaCl₂ \( (P = .0034) \) (Figure 4). Although hydrogels containing cells showed significantly higher calcium deposition than no cell controls following treatment with CaCl₂ (2.5 mM, \( P < .0001 \); 5 mM, \( P < .0001 \)) (Figure 4).

### 3.3 Immunohistochemical evaluation of NP cell phenotypic markers in the presence of cytokines and free Ca²⁺

NP phenotypic markers FOXF1, PAX1, and HIF1α were identified using IHC under nondegenerate standard control conditions and in the presence of cytokines and free Ca²⁺ (Figure 5). FOXF1 was seen at high
levels within monolayer culture, which was maintained within the NPgel cultures in standard culture (Figure 5). The percentage of cells immunopositive for FOXF1 was not affected by culture with CaCl₂ alone, however, culture with IL-1β, and/or TNFα in combination with 5 mM CaCl₂ significantly decreased FOXF1 expression compared to 5 mM CaCl₂ alone (5 mM CaCl₂ + IL1β + TNFα, P = .01; 5 mM CaCl₂ + TNFα, P = .0351; 5 mM CaCl₂ + IL1β + TNFα, P = .0106) (Figure 5). PAX1 expression was already expressed highly by monolayer MSCs and was not significantly altered in NPgel cultures under standard culture conditions. The percentage of cells immunopositive for PAX1 was not affected by culture with CaCl₂ alone (Figure 5). The cellular immunopositivity for PAX1 was significantly increased in the groups cultured in standard media with TNFα compared to standard culture alone (P = .0139) (Figure 5). Few MSCs in monolayer showed immunopositivity for HIF1α, which was increased in NPgel cultures (Figure 5). The number of cells with immunopositivity for HIF1α was increased in standard media with addition of IL-1β and TNFα in combination (P = .0493) (Figure 5). HIF1α was also increased following culture of MSCs in NPgel cultured in 5 mM CaCl₂ compared to standard culture (P = .0015) (Figure 5). Osteogenic differentiation determined by immunopositivity for osteopontin was not observed in the monolayer cultures, or in any NPgel culture conditions (Figure 5).

**FIGURE 2** Histological (Alcian Blue and Masson Trichrome) and immunohistochemical assessment (Aggrecan, collagen type II and collagen type I) of human mesenchymal stem cells (hMSCs) and acellular controls following culture for 4 weeks in Laponite crosslinked poly N-isopropylacrylamide-co-N, N'-dimethylacrylamide (NPgel) cultured under 5% O₂ under nondegenerate and degenerate culture conditions (5.0 mM CaCl₂ + IL1β + TNFα), together with monolayer controls. Black arrows indicate positively stained cells and white arrows indicate negatively stained cells. Scale bar 100 μm. Inlet shows magnified image of individual cells.
3.4 | Immunohistochemical evaluation of matrix degrading enzymes within MSCs cultured in NPgel

To assess hMSCs matrix degrading enzyme production within MSCs cultured within NPgel in the presence of cytokines and free Ca$^{2+}$, IHC was performed to assess the expression of MMPs 3, 13, and ADAMTs 4 (Figure 6). The percentage of cells immunopositive for MMP3 and MMP13 was significantly increased in all the cultures with 2.5 and 5 mM CaCl$_2$ compared to the nondegenerate standard control (MMP 3: 2.5 mM CaCl$_2$, $P$ = .0005; 5 mM CaCl$_2$, $P$ = .0005; MMP 13: 2.5 mM CaCl$_2$, $P$ = .0094; 5 mM CaCl$_2$, $P$ < .0001) and percentage of cells immunopositive for ADAMTS 4 was significantly increased following treatment with IL-1$\beta$ and TNF$\alpha$ ($P$ ≤ 0.05) (Figure 6). The costimulation with cytokines had no further influence on the percentage of cells which displayed IHC for MMPs or ADAMTs (Figure 6).

3.5 | Immunohistochemical evaluation of catabolic mediators in the presence of cytokines and free Ca$^{2+}$

Immunocytochemistry was performed to assess the expression of known catabolic mediator: IL-1$\beta$ and its receptor IL-1RI in monolayer cultures and following embedding into hydrogel alone and following culture in CaCl$_2$. The percentage immunopositivity for endogenous IL-1$\beta$ and its receptor (IL-1RI) were decreased under nondegenerate standard culture conditions following embedding into the hydrogel, in comparison to the monolayer controls (IL-1$\beta$: $P$ = .0216; IL-1RI: $P$ = .0014) (Figure 7). While the percentage of cells immunopositive for endogenous IL-1$\beta$ significantly increased when cultured with 2.5 mM CaCl$_2$ and 5 mM CaCl$_2$ compared to standard hydrogel cultures and IL-1RI increased following culture in hydrogels with 5 mM CaCl$_2$ (IL-1$\beta$: 2.5 mM CaCl$_2$: $P$ = .0216; IL-1RI: $P$ = .0014) (Figure 7).
CaCl$_2$, $P = .0003$; 5 mM CaCl$_2$, $P = .0001$; IL-1RI: 5 mM CaCl$_2$, $P = .0052$) (Figure 7).

### 4 | DISCUSSION

We have previously reported a synthetic Laponite crosslinked pNIPAM-co-DMAc (NPgel) hydrogel, which induces NP cell differentiation of hMSCs without the need for additional growth factors.\(^{45}\) This differentiation in the absence of growth factors is likely to be due to the highly hydrated nature of the hydrogel, together with similar mechanical properties and O$_2$ concentration to native NP tissue which appears to provide the appropriate cues supporting differentiation. Furthermore NP gel supports integration following injection into the disc and restores mechanical function to the disc.\(^{44}\) This hydrogel system provides a potential approach for there generation of the degenerate disc, however the successful translation is dependent on understanding the cell behaviour within the degenerate niche. Thus,
FIGURE 5  A: Immuno-histochemical detection of nucleus pulposus (NP) phenotypic markers: FOXF1, PAX1 and HIF-1α, and NP negative marker: osteopontin in human mesenchymal stem cells (hMSCs) in monolayer culture and resuspended in Laponite crosslinked poly N-isopropylacrylamide-co-N, N’-dimethylacrylamide (NPgel) and acellular controls following culture for 4 weeks in 5% O₂ under nondegenerate and degenerate culture condition (5.0 mM CaCl₂ + IL1β + TNFα). Scale bar 100 μm. Inlet shows magnified image of individual cells. here, we investigated the viability and differentiation of hMSCs within the L-pNIPAM-co-DMAc hydrogel (NPgel) within a hostile catabolic microenvironment associated with degeneration,28–36 a 4 week time-point was selected as this has been shown previously to be sufficient to support MSC differentiation within NPgel toward NP like cells.45 These studies aimed to determine, whether combination therapies to inhibit the degenerate niche would be necessary to improve the likelihood of success for MSC applications. Thus, highlighting the importance of identifying clinical targets based on severity of degeneration which could have key implications for successful treatment outcomes.

The metabolic activity of hMSCs incorporated within NPgel was maintained throughout all the degenerate culture conditions. FIGURE 6 A: Immunohistochemical detection of matrix turnover markers: MMP3, MMP13, and ADAMTS4 in human mesenchymal stem cells (hMSCs) encapsulated in Laponite crosslinked poly N-isopropylacrylamide-co-N,N'-dimethylacrylamide (NPgel) cultured under nondegenerate (standard media control) and degenerate conditions (5.0 mM CaCl2, ± IL1β + TNFα) for 4 weeks. Black arrows indicate positively stained cells and white arrows indicate negatively stained cells. Scale bar 100 μm. Inlet shows magnified image of individual cells. B: Percentage immunopositivity was calculated and statistical analysis performed * indicates significant difference between percentage immunopositivity following CaCl2 treatment compared to standard media controls, † indicates significant difference following treatment with interleukin-1β (IL-1β), ‡ indicates significant difference following treatment with tumor necrosis factor alpha (TNFα), and § indicates significant difference following treatment with IL-1β and TNFα (P ≤ 0.05)
However, proliferation was not evident, possibly due to a focus on cellular differentiation, or structural limitations of the three-dimensional (3D) hydrogel construct. We have previously reported this phenomenon and an associated reduction in pore size as a result of matrix deposition within the hydrogel in vitro. Here, within this study, immunohistochemical analysis of the apoptotic marker caspase 3, showed increased levels of apoptosis of the differentiated hMSCs in the presence of multiple cytokines and/or calcium, although at low levels (≤20% apoptotic) compared to the nondegenerate standard culture model, suggesting the degenerate niche may induce apoptosis to low levels. This agrees with previous studies where native NP cells within the degenerate disc have been shown to display increased levels of apoptosis and senescence. However, the clinical implication of these low levels of apoptosis is likely to be minimal.

In agreement with previous findings, this study demonstrated that hMSCs incorporated into NPgel and cultured under hypoxic non-degenerate conditions in vitro, induces differentiation of hMSCs into NP-like cells without the need for additional growth factors. Here, we have shown that MSCs incorporated into NPgel, cultured within a hypoxic, noncatabolic environment (i.e., in the absence of cytokines and calcium), produced NP matrix components: collagen type II, aggrecan, and NP markers. Unfortunately due to the nondegradable nature of the hydrogel, it is not possible to perform quantitative biochemical analysis or gene expression analysis on these systems and

![FIGURE 7](image_url)
IHC was deployed to investigate changes in cellular expression of proteins. Interestingly, hMSCs also expressed NP matrix components collagen type II and aggrecan even in the presence of the cytokines and free Ca$^{2+}$. The ability of hydrogel encapsulated hMSCs to differentiate into NP like cells capable of producing NP like matrix components even in the presence of cytokines and free Ca$^{2+}$ is extremely promising as a treatment strategy for regeneration of the IVD.

Previous studies have shown that NP cells upregulate the expression of MMP3, MMP13, and ADAMTS 4 in response to treatment with IL-1$\beta$ and TNF$\alpha$.[33,47–49] Here, where hMSCs were treated with IL-1$\beta$ or TNF$\alpha$ alone, or in combination, no significant difference in immunopositivity was observed for MMP3, MMP13, and ADAMTS 4. Interestingly, studies have shown that MSCs in monolayer display an increase in MMP expression in response to cytokines,[50,51] while this was not seen in hMSCs cultured within NPgel. Studies have shown that 3D culture systems are advantageous for stem cell differentiation, increase therapeutic potential, and enhance anti-inflammatory properties of MSCs.[52,53] Here, we have shown that hMSC expression of endogenous IL-1$\beta$ and IL-1$\alpha$ was decreased where MSCs were incorporated into hydrogel when compared to the monolayer controls. The exact mechanism by which NPgel induces these protective roles is not clear but could be due to the similar mechanical properties to native normal NP disc and culture within a hydrated 3D system. Our combination therapy therefore exhibits an advantageous mechanism over other proposed therapies[43] within the catabolic degenerate disc, further work is required to determine the exact cellular mechanism for the protective effects seen here.

When Ca$^{2+}$ was present within the degenerate culture conditions, a significant increase in calcium deposition was observed in MSC-laden NPgel cultures compared to the acellular controls. This has also been observed in isolated disc cells and healthy caudal IVDs cultured in the presence of increased Ca$^{2+}$.[36] Furthermore, an increase in the expression of collagen type I, MMP3, MMP13, and ADAMTS 4 was observed. MMP13 has been previously shown to be increased in chondrocytes in response to accumulated calcium phosphate crystals in osteoarthritis.[54] This could suggest that calcium treatment and subsequent deposition alters the phenotype and differentiation of hMSCs, possibly to a more accelerated degenerate phenotype. MSCs have also previously been shown to undergo osteogenic differentiation in the presence of Ca$^{2+}$.[55,56] and here, we observed an increase in collagen type I that could indicate possible osteogenic differentiation, although osteopontin was not induced. This could have an impact on the ability of hMSCs to regenerate appropriate mechanically functional matrix and so poses the question, in disc degeneration where calcification is present, will the differentiation of MSCs be altered adversely. Importantly, this could have key implications for treatment during late stage degeneration where calcification is often observed.[36,57,58]

The next stages will be to recapitulate the other features seen within the degenerate niche, including decreased osmolality, pH, nutrients, and mechanical load to fully understand how the mesenchymal stem cells delivered via NPgel will behave within the degenerate disc. Furthermore the work reported in this paper has been performed on commercially derived MSCs which are limited by patient variation and thus it is essential to investigate the behavior of patient stem cells within the hydrogel to determine patient variation within the NPgel system.

5 | CONCLUSION

MSCs embedded within Laponite crosslinked pNIPAM-co-DMAc hydrogel (NPgel) and cultured under conditions to simulate the degenerate niche (cytokines and calcium) retained their differentiation ability, expressing aggrecan, and collagen type II. However, calcium treatments increased expression of degradation enzymes and inappropriate matrix components, highlighting the potential role of calcium in degeneration and the importance to consider the severity and stage of disc degeneration when targeting such a therapy. Importantly, the Laponite crosslinked pNIPAM-co-DMAc hydrogel described here, not only has the potential to provide mechanical support and deliver MSCs for regeneration of the IVD, but also may simultaneously function to protect delivered MSCs from the catabolic environment in degeneration.

AUTHOR CONTRIBUTIONS

L.V. performed the majority of the laboratory work, and data analysis, contributed to study design, helped to secure funding, and drafted the manuscript. A.A.T. and J.S. contributed to the laboratory work, data analysis, study design, and critically revised the manuscript. C.S. and C.L.L.M. conceived the study, participated in its design and coordination, aided in the analysis of data, secured funding, and critically revised the manuscript. All authors read and approved the final manuscript.

ACKNOWLEDGMENTS

We would like to offer kind thanks to the Biomolecular Sciences Research Centre, and the Materials Engineering Research Institute at Sheffield Hallam University for funding the Daphne Jackson Fellowship of L.V. The authors thank funding from the MRC, grant ref: MR/P026796/1.

CONFLICT OF INTEREST

C.L.M. and C.S. are named inventors on a patent for the L-pNIPAM hydrogel described here.
