Triphenylarsenium-functionalised gold nanoparticles: potential nanocarriers for intracellular therapeutics†

Two new triphenylarsenium alkylthiolate precursors, a thiosulfate zwitterion and a thioacetate salt, have been structurally characterised and their cytotoxicity evaluated against PC3 cells. The arsonium compounds have been used to prepare gold nanoparticles decorated with triphenylarsenium groups.

Arsenic has attracted the attention of scientists for centuries and its compounds have a variety of applications ranging from electronic and semiconductor materials1 to organic reagents, arsonium ylides finding utility in the Wittig reaction.2 Historically, arsenic compounds have been widely investigated for their medicinal properties although interest declined as greater understanding of their toxicity became apparent.3,4 Generally inorganic As(III) and As(V) species are highly toxic, whereas organic arsenic compounds are significantly less toxic.1,5 More recently there has been a resurgence of interest in the medicinal properties of arsenic compounds, including the use of arsine trioxide and organic arsenic derivatives as treatments for leukaemia and other cancers,1,3,4 the characterisation of an arsenic trioxide analogue of cisplatin,6 and the observation that arsonium cations are also lipophilic and that the negative charge is delocalised over the character, and that the negative charge is delocalised over the molecular structure (Fig. 1), the S–O bonds in the thiosulfate group are similar to those in thioacetate salts, have been structurally characterised and their application in the synthesis of triphenylarsenium-functionalised gold nanoparticles (AuNPs).

The synthesis of 3, 4 and the triphenylarseniumalkylthiolate-functionalised AuNPs are described in the ESI.† The structures of 3 and 4 were confirmed by X-ray crystallography. Perhaps surprisingly, the structures of few organic thiosulfate zwitterions have been reported.18 Both compounds display the expected tetrahedral geometry around the arsenic atoms with mean C–As–C bond angles of 109.5(2)° in 3 and 109.46(11)° in 4. In zwitterion 3 (Fig. 1), the S–O bonds in the thiosulfate group are similar with a mean length of 1.447(4) Å, indicative of multiple bond character, and that the negative charge is delocalised over the

Using MTT and CellTitre-Glo the PC3 prostate cancer cell line. Cell viability was assessed of chemical entities. The results showed range 0.4–5 m for example, the IC50 of sodium arsenate was reported as 6 μM. In contrast, the organic derivative arsenobetaine, Me3As(CH2CO2)−, an important metabolite of arsenic which is widely distributed in marine ecosystems and found in comparatively high levels in seafood, is reported to have no toxic effects and was found to significantly enhance the cell viability of bone marrow cells in vitro in a concentration-dependent manner.

Phosphonioalkylthiosulfate zwitterions, and phosphonium alkylthioacetate salts, are known to act as ‘masked thiolates’ and under reductive conditions cleavage of the thiosulfate S–S or thioacetate S–C bonds, respectively, takes place, generating phosphonioalkylthiolate zwitterions that can coordinate to the surface of gold films.

We have exploited this chemistry to generate water-soluble cationic gold nanoparticles functionalised with alkylthiolate ligands bearing phosphonium head-groups. We have now extended this approach to the analogous arsionium compounds. Reduction of tetrachloroauroate salts in situ with sodium borohydride in the presence of 3 or 4 in a biphasic water/dichloromethane mixture yields the triphenylarsonium-capped AuNPs. Recent work has reported rare examples of the coordination chemistry of tertiary arsine ligands bearing pendant thiolate groups towards Ni(n), Pt(n) and Pd(n). However, to the best of our knowledge, there are no reports of the coordination chemistry of triorganoarsionium thiolate species or of the use of tertiary arsines or arsionium compounds as capping ligands in the formation of functionalised nanoparticles, although nanoscale liposomes or nanobins, composed of lipids and metal salts, have been used to encapsulate and stabilise arsenic trioxide in order to extend the clinical utility of this compound.

CellTitre-Glo assay to confirm the MTT cytotoxicity data. This uses luminescence to determine the number of viable cells based on a quantification of ATP levels. The data showed a similar trend to that determined using MTT.

The cytotoxicity of arsenic compounds is crucially dependent on the nature and oxidation state of the species. Inorganic compounds, such as arsenite and arsenate, show acute toxicity; for example, the IC50 of sodium arsenate was reported as 6 μM.

In order to evaluate the efficacy of the triphenylarsonium-functionalised AuNPs as cellular transport systems we first screened the parent arsionium compounds 3 and 4 against the PC3 prostate cancer cell line. Cell viability was assessed using MTT and CellTitre-Glo® assays (Fig. 3). MTT measures mitochondrial activity to determine the in vitro cytotoxic effects of chemical entities. The results showed 3 and 4 to have IC50 values of 75 μM and 72 μM, respectively, after 72 hours. These values compare very favourably with those of phosphonium compounds, a large number of which have been screened using MTT against PC3 cells, and which displayed IC50 values in the range 0.4–5 μM. These results are also in accordance with cellular toxicity data for lipophosphoramidate derivatives, where phosphonium compounds show greater cytotoxicity than the corresponding arsionium compounds. We also used the entire sulfate group. The mean O–S–O angle [113.8(2)°] is consistent with those in other thiosulfate ions. The S–S bond length [2.1081(18) Å], is slightly shorter than that of the corresponding phosphonium compound [2.1117(9) Å], but longer than the S–S bond in ionic thiosulfate ions such as Me2HN(CH2S2O3)2− Na+ . Within the crystal lattice the zwitterions pack fairly loosely, held together by hydrogen-bonding interactions between the sulfate oxygens and the phenyl hydrogens, but there is no close interaction between the arsonium and the thiosulfate moieties. The bond lengths and angles of the thioacetate group in salt 4 (Fig. 2), are as expected. The molecular packing shows no significant interactions between the arsonium centre and the bromide anion or between the bromide and the carbonyl group.

Fig. 4 TEM image of arsonium-AuNP derived from zwitterion 3 and associated particle size histogram.

The triphenylarsonium-AuNPs can be purified by extraction with dichloromethane followed by freeze drying. The UV-Vis spectrum of a typical sample of arsonium-capped nanoparticles shows an absorption band with $\lambda_{\text{max}}$ of 520 nm. High resolution TEM analysis of the AuNPs derived from the thiosulfate zwitterions is shown in Fig. 4, and revealed the AuNPs to have spherical shapes. Size distribution analysis of 1000 particles using Abel imaging software revealed a mean diameter of 2.7 nm. Wide scan XPS spectra of the arsonium-AuNPs contained signals due to Au (4f7/2) and Au (4f 5/2) with binding energies of ca. 83.9 and 87.5 eV respectively, indicative of the presence of Au(0). Research is now ongoing to understand the cellular uptake and transport properties.
